

# Computer Vision with Real-World Data

Student	Danila Moskvitin
Student's time capacity	$8 \pm 3$ hours
Simulation time capacity (GPU: 20 GB VRAM)	$10 \pm 5$ hours

## General Instruction

Please use Russian or English language when preparing this document, but not their mixture. The exception is for the code in the Appendix section which may be a mixture of operators in English and comments in Russian.

Students are welcome to use any tool that is suitable for preparing high-quality work. However, we ask students to keep in mind two important criteria. First, we expect students to fully describe their methodology, and any tool that is important to that methodology, including the use of LLMs, should be described also. For example, students should mention tools (including LLMs) that were used for data processing or filtering, visualization, facilitating or running experiments, reviewing, coding, translating, proving theorems, etc. It may also be advisable to describe the use of LLMs in implementing the method (if this corresponds to an important, original, or non-standard component of the approach). Second, students are responsible for the entire content of their work, including all text and figures, so while students are welcome to use any tool they wish for writing, they must ensure that all text is correct and original.

A few practices are strongly discouraged: plagiarism, falsification, and any other methods that divert students' internal resources and abilities away from truly immersing themselves in solving this assignment.

So, the goal should not be to avoid challenges or merely achieve formal results, such as grades, but to engage deeply with the material and develop meaningful solutions.

## Goals

The primary goals of this assignment are for students to:

1. Learn how to work with real-world data that may contain human labeling errors.
2. Understand how to design AI systems that account for uncertainty and doubt.
3. Explore methods and model configurations to enhance robustness when dealing with imperfect data.

To achieve these goals, students will compare three types of loss functions in the context of a classification problem: the *cross entropy loss* (CE loss), as a standard loss function for classification tasks; a *custom loss*, called B-loss (ideally, adapted or created by the student) that can estimate the uncertainty of the model's predictions; the *Heteroscedastic Regression Loss based on a multivariate normal distribution* (N-loss) which is normally used in fitting problems and which capable of estimating the uncertainty of the model's predictions in classification.

Through this comparison, students will gain insights into how different loss functions handle imperfect data and how to make models more resilient to such challenges.

## Tasks and Requirements

The following points should be met:

1. Fill your name in the form above
2. Review the dataset CIFAR-10N and related work
3. Check the proposed methodology on loss functions, ensembling and metrics
4. Implement the proposed methodology in code for training an ensemble with a given loss and a list of seeds
5. Implement the label smoothing techniques and alternative ways to calculate final ensemble predictions using majority voting and weighted predictions (check your personal task with an instructor)

Figure 1: Schematics of the classification models under study: the CE-model serves as the baseline (see Equation (11)), the B-model includes an additional output  $c \in (0, 1)$  that calculates the certainty value of the prediction  $h$  (see Equation (7)), and the N-model introduces an additional output  $s \in (-\infty, \infty)$  that computes the logarithmic variance of the prediction (see).

6. Perform a computational experiment, fill the table and figure of the results
7. Fill in the remaining sections of the report, including Related work, Results and discussion, Conclusion, and Introduction
8. Submit the code and report

**Bonus (complete one of the following points as a bonus task):**

1. Revise the proposed B-model or N-model, enhance it and obtain higher metrics in additional experiments
2. Implement a more advance ANN, e.g. using recommendations from papers related to CIFAR-10N dataset
3. Achieve the original results with accuracy of top 10 solutions in accordance with SOTA rating for CIFAR-10N

**Sections that require revision and completion:** 1, 2, 4, 5, 6.

## Evaluation Criteria

The work will be evaluated based on the following criteria:

1. **Basic Level (65–75%):**
  - The main tasks have been completed.
  - Verifiable results have been obtained.
  - A well-formatted written report and the main code have been submitted.
2. **Intermediate Level (76–89%):**
  - The approach to solving the problem and the results obtained demonstrate originality.
  - Additional efforts have been made to achieve better results.
  - The work is neatly presented and shows a deep understanding of the topic.
3. **Advanced Level (90–100%):**
  - One of the *bonus track* questions has been solved, or results exceeding basic expectations have been achieved.
  - The work demonstrates exceptional quality, creativity, and independence.

## 1 Introduction

**Learning with Real-World Human Annotations.** Deep learning models are highly sensitive to the choice of loss functions, regularization techniques, and the quality of training data, particularly in the presence of label noise. This work investigates the impact of different loss functions and label smoothing on neural network performance using the CIFAR-10N dataset, which includes both clean and noisy labels (aggregate variant). We compare models trained on clean and noisy data, evaluating their robustness to label noise. Additionally, we explore the effectiveness of model ensembling (majority voting) as a strategy to improve performance and stability. Our experiments aim to provide insights into how loss functions and ensembling interact in noisy label scenarios.

## 2 Related work

Learning with Noisy Labels (LNL) addresses the challenge of training models on imperfect datasets. Modern methods include loss correction, sample selection, and semi-supervised learning (SSL). Approaches like **DivideMix** and **Co-Teaching** use small-loss strategies to separate clean and noisy samples, but often misclassify hard samples as noisy. **ProMix** dynamically expands the clean set and uses debiased SSL to mitigate confirmation bias. **PSSCL** decouples sample selection from SSL training, integrating contrastive learning (CL) for robustness under high noise. Similarly, **PGDF** leverages training history to distinguish hard samples, improving pseudo-label quality. These methods advance LNL by addressing limitations of existing approaches and providing robust solutions for real-world applications.

**Uncertainty-aware objectives.** One of the approaches to uncertainty estimation of the regression models is the *heteroscedastic* regression that takes both the variable mean and variance into account [18, 20]. So, the model trains to predict means and variances, and the uncertainty of the model predictions can be estimated using the variance values. Fortunately, classification models can also use a *squared error* (SE) loss. Hui and Belkin [10] demonstrated that the SE and CE-based computer vision models are close in accuracy. However, a SE loss needs some more training epochs. Kendall and Gal [11] dealt with two types of uncertainty, that are aleatoric (data uncertainty) and epistemic (model uncertainty), and proposed two approaches in uncertainty estimation. Kendall and Gal [11] declared that out-of-data examples cannot be identified with aleatoric uncertainty. The authors also proposed an approach that combines aleatoric and epistemic uncertainties. Further work by van Amersfoort et al. [22] deals with the deterministic uncertainty quantification method. The proposed model learns the positions of centroids of classes and trains kernels to estimate the distance between an input sample and centroids, which allows the inference model to recognize an out-of-data sample as uncertain. Sensoy et al. [21] developed a theory of evidence perspective and represented the model predictions as a Dirichlet density distribution over the softmax outputs and proposed a novel loss function. Collier et al. [3] proposed a method for training deep classifiers under heteroscedastic label noise. The method deals with the softmax temperature tuning that allows to control a bias-variance trade-off.

**Ensembling, test-time augmentation, and label smoothing.** Ashukha et al. [1] demonstrated that many ensembling techniques are equivalent to an ensemble of several independently trained networks in terms of test performance. Test-time augmentation is a technique that improves model performance using averaging the predictions [14]. Probably the simplest ways to make models be more robust to noise in labels are label smoothing [23] and data augmentation [19].

**Data uncertainty estimation in practice** Corrupted inputs [13] and corrupted labels [26], in-domain and out-of-domain distributions [15, 11, 3] are some of the poles of the research in the scope of data uncertainty estimation. The typical test of the models in practice is to use public datasets with corrupted (noisy) labels at the training and validation stages but with clean labels at the test stage [25, 26]. A number of methods try to detect input samples with incorrect labels and remove [3, 25, 26] or under-weight these samples [11, 4]. Han et al. [8] declared that models learn data with clean labels first and noisy labels then, and proposed a new paradigm called *co-teaching* with the training of two networks.

## 3 Methodology

In general, consider a model  $\mathbf{f}[\mathbf{x}, \mathbf{w}]$  parameterized by weights  $\mathbf{w}$  that maps an input  $\mathbf{x}$  into logits  $\mathbf{z}$  first and then into the hypothesis  $\mathbf{h}$  that approximates the ground truth  $\mathbf{y}$ . The negative log-likelihood minimization [18, 2, 6] allows the formalization of the following uncertainty-aware loss functions for fitting and classification problems using different types of distributions for the outputs of the models.

### 3.1 B-loss

This paragraph presents a specific interpretation of a binary classification model based on minimizing the *uncertainty-aware negative log-likelihood with the Bernoulli distribution* (B-model, B-loss). The proposed model is trained to ensure that true predictions are made certain and false predictions if they occur, are made uncertain (see fig. 2). The binary classifier estimates the certainty value  $c \in (0, 1)$ , which is the primary task in the proposed formalization. Additionally, the classifier estimates and enhances the similarity  $\delta$  between the hypothesis  $\mathbf{h}$  and the ground truth  $\mathbf{y}$ , which constitutes the secondary task in the proposed formalization.

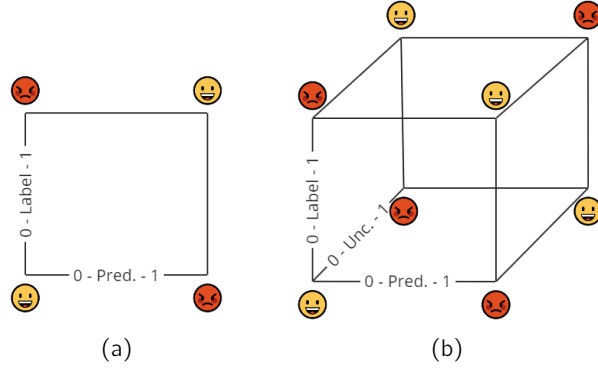

Figure 2: Binary classification intuition with the BCE loss (a) and the proposed binary B-loss eq. (4) (b) with respect to the values of the model's outputs (uncertainties  $u = 1 - c$ , predictions  $h$ ), and labels  $y$ .

**Binary classification.** Consider an  $i^{\text{th}}$  sample and a model with logits  $z^{(i)} = [z_{\text{pred}}^{(i)}, z_{\text{cert}}^{(i)}]$  which correspond to a prediction  $h^{(i)} = \sigma(z_{\text{pred}}^{(i)})$ , and the certainty  $c_i = \sigma(z_{\text{cert}}^{(i)})$  associated with the prediction, respectively. Then, compare the prediction  $h^{(i)}$  and the given label  $y^{(i)}$  using a scalar product metric  $\delta_i = y^{(i)} h^{(i)}$ , and map this metric as a pseudo-label of a binary uncertainty estimator into the parameters of a Bernoulli probability mass function [18]:

$$p_i = p(\delta_i | c_i) = \begin{cases} 1 - c_i & \text{if } \delta_i \rightarrow 0, \\ c_i & \text{if } \delta_i \rightarrow 1, \end{cases} \quad (1)$$

where  $\delta_i \in (0, 1)$  is the smoothed pseudo-label that characterizes the similarity between the label and the prediction.

eq. (1) is a discrete probability distribution for a random variable that takes the value 0 with probability  $1 - c_i$ , which is an incorrect prediction that corresponds to an uncertainty of the prediction, and the value 1 with probability  $c_i$ , which is a right prediction that corresponds to a certainty of the prediction. The Bernoulli distribution has an equivalent power law form [18]:

$$p_i = c_i^{\delta_i} (1 - c_i)^{1 - \delta_i}. \quad (2)$$

For a roll-out of dataset of  $m$  i.i.d. pairs  $\{x^{(i)}, y^{(i)}\}$  associated with the outputs of the model  $\{h^{(i)}, c_i\}$ , the joint probability [2] for the given probability mass function eq. (2) takes the following form:

$$P(\delta_1, \dots, \delta_m | c_1, \dots, c_m) = \prod_{i=1}^m c_i^{\delta_i} (1 - c_i)^{1 - \delta_i}. \quad (3)$$

The negative logarithm of the joint probability eq. (3) represents the proposed uncertainty-aware B-loss for the binary classification:

$$\mathcal{L}_B = -\frac{1}{m} \sum_{i=1}^m [\delta_i \log c_i + (1 - \delta_i) \log(1 - c_i)]. \quad (4)$$

eq. (4) intuition is demonstrated in fig. 2. The B-loss can be generalized for the case of multiclass classification.

**Multiclass (N-classes) classification.** Consider an  $i^{\text{th}}$  sample and a model with logits  $\mathbf{z}^{(i)} = [\mathbf{z}_{\text{pred}}^{(i)}, z_{\text{cert}}^{(i)}]$  which correspond to a vector of prediction  $\mathbf{h}^{(i)} = \text{softmax}(\mathbf{z}_{\text{pred}}^{(i)})$ ,  $\mathbf{h}^{(i)} \in \mathcal{R}^N$ , and the certainty  $c_i = \sigma(z_{\text{cert}}^{(i)})$  associated with the prediction, relatively. Then, compare the prediction vector  $\mathbf{h}^{(i)}$  and the given one-hot encoded label vector  $\mathbf{y}^{(i)}$  using a scalar product terms  $\delta_k^{(i)} = y_k^{(i)} h_k^{(i)}$ , and map this metrics as pseudo-labels into a probability mass function:

$$p_i = \prod_{k=1}^N \left( \frac{c_i}{N} \right)^{\delta_k^{(i)}} \left( \frac{1 - c_i}{N} \right)^{1 - \delta_k^{(i)}}, \quad (5)$$

where  $\delta_k^{(i)} \in (0, 1)$  is the smoothed one-hot encoded pseudo-label that characterizes the similarity between the  $k^{\text{th}}$  components of the label and the prediction vectors,  $N$  is the number of classes.

Following the logical sequence given in section 3.1 and in [18], the joint probability for eq. (5) can be obtained, and then transformed into the negative log-likelihood (NLL):

$$NLL = -\frac{1}{m} \sum_{i=1}^m \left( \cos(\mathbf{h}^i, \mathbf{y}^i) \log \left( \frac{c^{(i)}}{N} \right) + (N - 1) (1 - \cos(\mathbf{h}^i, \mathbf{y}^i)) \log \left( \frac{1 - c^{(i)}}{N} \right) \right), \quad (6)$$

where  $\cos(\mathbf{h}^i, \mathbf{y}^i)$  is the smoothed pseudo-label that characterizes the cosine similarity between two N-dimensional vectors: the vector of prediction and the one-hot encoded label vector.

Finally, the proposed uncertainty-aware B-loss for the N-classes classification is the Kulback-Loeberg divergence between two distributions: the one-hot encoded smoothed pseudo-labels distribution and the NNL distribution eq. (6):

$$\mathcal{L}_B = \frac{1}{m} \sum_{i=1}^m \sum_{k=1}^N \delta_k^{(i)} \log \delta_k^{(i)} + NLL. \quad (7)$$

where  $m$  is the number of samples (in a batch),  $N$  is the number of classes,  $\delta_i = y^{(i)} h^{(i)}$  are the terms of a scalar product of the one-hot encoded label vector and the vector of prediction of the model,  $c^{(i)}$  is the certainty of the prediction (fig. 1b).

### 3.2 N-loss

Since the binary classification can be assumed as a particular case of a multiclass classification, this section skips the binary classification paragraph.

**Multiclass classification.** Consider an  $i$ -th sample and a model with logits  $\mathbf{z}^{(i)} = [\mathbf{z}_{mean}^{(i)}, \mathbf{z}_{var}^{(i)}]$  which maps into the parameters of a multivariate normal distribution: the hypothesis or mean  $\mathbf{h}^{(i)} = \mathbf{z}_{mean}^{(i)}$  that approximates the ground truth  $\mathbf{y}^{(i)}$ , and the variance  $\sigma_{(i)}^2 = \exp(\mathbf{z}_{var}^{(i)})$  that characterizes the uncertainty of the hypothesis,  $f[\mathbf{x}^{(i)}, \mathbf{w}] = [\mathbf{h}^{(i)}, \sigma_{(i)}^2]$ . In other words, it is assumed that the conditional probability distribution  $p = p(\mathbf{y}^{(i)} | \mathbf{x}^{(i)}) = p(\mathbf{y}^{(i)} | \mathbf{f}[\mathbf{x}^{(i)}, \mathbf{w}])$  has the form of a multivariate normal distribution characterized by equal variances (spherical covariances) in N-dimensional space [17]:

$$p^{(i)} = \frac{\exp\left(-\frac{\sum_{k=1}^N (y_k^{(i)} - h_k^{(i)})^2}{2\sigma_{(i)}^2}\right)}{(2\pi\sigma_{(i)}^2)^{\frac{N}{2}}}, \quad (8)$$

The multivariate normal distribution of (8) can be applied to the negative log-likelihood criterion of an uncertainty-aware negative log-likelihood loss (N-loss) for the regression [18]:

$$\mathcal{L}_N = \frac{1}{2m} \sum_{i=1}^m \left( \sum_{k=1}^N \frac{(y_k^{(i)} - h_k^{(i)})^2}{\sigma_{(i)}^2} + N(s^{(i)} + r) \right), \quad (9)$$

where  $m$  is the number of samples (in a batch),  $\mathbf{y}^{(i)}$ ,  $s^{(i)} = \log \sigma_{(i)}^2$  is the log-variance,  $r = \log 2\pi$  is the constant value.

The last term in (9) represents a constant that can be neglected. Kendall et al. [11] recommended to train the models to predict log-variances  $s^{(i)} = \log \sigma_{(i)}^2$ , because it is more numerically stable than the variance  $\sigma_{(i)}^2$  and the loss avoids a potential division by zero:

$$\mathcal{L}_N = \frac{1}{m} \sum_{i=1}^m \left( e^{-s^{(i)}} \sum_{k=1}^N (y_k^{(i)} - h_k^{(i)})^2 + Ns^{(i)} \right). \quad (10)$$

Thus, (10) represents a heteroscedastic regression loss [18, 11], generalized for the case of a space of N dimensions. Our proposal is to use this loss for classification problems.

The baseline loss in a multi-class classification problem is the cross-entropy loss [6, 18, 2]:

$$L_{CE} = -\frac{1}{m} \sum_{i=1}^m \sum_{k=1}^N y_k^{(i)} \log h_k^{(i)}. \quad (11)$$

### 3.3 Ensembling

A set of  $q$  models  $\mathbf{f}_1, \mathbf{f}_2, \dots, \mathbf{f}_q$  with different random initialization of the weights are trained with the same dataset. This aggregation reduces overfitting and provides more robust estimates by averaging out individual model errors [1]. Each  $j^{\text{th}}$  model predicts a class index for the given  $i^{\text{th}}$  input:

$$\hat{y}^{(ij)} = \arg \max_k h_k^{(ij)}, \quad (12)$$

Figure 3: Ensemble of  $q$  models makes the prediction  $\mathbf{h}$  for the  $q$  augmented copies of an input sample  $\mathbf{x}$ . Two-classes classification is demonstrated.

where  $i, j, k$  are the dummy indexes that refer to  $j^{\text{th}}$  augmented version of  $i^{\text{th}}$  sample, and  $k^{\text{th}}$  component of the prediction vector or class index,  $i \in (1, m), j \in (1, q), k \in (0, N - 1)$ .

The final ensemble prediction class is typically determined by *majority voting* based on the class predictions of the individual  $j^{\text{th}}$  model.

$$\hat{y}^{(i)} = \text{mode} \left( \hat{y}^{(i,1)}, \hat{y}^{(i,2)}, \dots, \hat{y}^{(i,q)} \right). \quad (13)$$

The final ensemble prediction class can also be determined by *confidence-based weighted predictions* (see fig. 3). Each model predicts a class  $\hat{y}^{(i,j)}$  and provides a confidence value  $co^{(i,j)}$  for its prediction:

$$co^{(i,j)} = \max_k (h_k^{(i,j)}). \quad (14)$$

The aggregated confidence for class  $k$  is:

$$co_k^{(i)} = \sum_{j=1}^q co^{(i,j)} \cdot \mathbb{I} \left( \hat{y}^{(i,j)} = k \right), \quad (15)$$

where  $\mathbb{I}(\cdot)$  is the indicator function, which returns 1 if the condition is true and 0 otherwise,  $co_k^{(i)}$  is the total confidence for class  $k$  across all models.

The final predicted class is:

$$\hat{y}^{(i)} = \arg \max_k co_k^{(i)}. \quad (16)$$

The uncertainty estimation in deep ensembling is derived from the variance of the individual model predictions. Higher variance among the models' outputs indicates greater uncertainty, providing a measure of epistemic uncertainty.

### 3.4 Metrics

The standard classification metrics for the balanced datasets are the accuracy, receiver operating characteristic - area under curve (ROC-AUC) [2, 6]. A set of more specific metrics used in uncertainty quantification involves estimation the confidence (see eq. (14)) [15]: the Brier score, the entropy, the expected calibration error (ECE), the negative log-likelihood (NLL), the prediction interval coverage probability (PICP), the sharpness, etc. [16, 7, 5, 9].

Since the proposed B-model (see eq. (7)) and N-model (see eq. (10)) have an extra output, the following additional *certainty* metrics can be met:

- $c^{(i)} \in (0, 1)$  for the B-model ;
- $1 - \text{sigm}(s^{(i)}) \in (0, 1)$  for the N-model.

Both of the above metrics can be used as weights in eq. (16), thus the *certainty-based weighted predictions* should be met.

## 4 Results and Discussion

CIFAR-10N dataset [24] was split into training, validation, and test sets in the amounts of [45000, 5000, 10000] samples, respectively. The models were trained with a 9-layer convolutional neural network [8, 25]. The network has 4.4 million parameters that were randomly initialized during training. The CNN architecture and most of the settings correspond to the experiments by Xia et al. [25] with minor changes: the models were trained for 20 epochs (200 in the original paper) using the Adam optimizer with a momentum of 0.9 and a batch size of 128, and a constant learning rate of 0.001 (in the original paper, the initial learning rate linearly decreased to zero starting from

Table 1: Accuracy (%) of models trained on the CIFAR-10N dataset with clean and noisy labels, as well as with label smoothing (LS). Each model was trained using seven different weight initialization seeds for 20 epochs, then ensembled. The mean test accuracy of individual models is compared with the accuracy of the ensemble using majority voting (EMV). The best results are highlighted in bold.

Method	Arch.	#Param. (train.par.)	LS	Accuracy (single model / EMV),%	
				Clean	Noisy (aggre)
Baseline CE loss	9-l.CNN	4.4 M (all)	0.1	86.44 $\pm$ 0.003/ <b>89.37</b>	82.66 $\pm$ 0.003/86.01
Proposed B-loss	9-l.CNN	4.4 M (all)	0.1	84.49 $\pm$ 0.002/88.20	82.79 $\pm$ 0.003/ <b>86.20</b>
Proposed N-loss	9-l.CNN	4.4 M (all)	0.1	85.58 $\pm$ 0.002/88.27	83.34 $\pm$ 0.001/86.17
Proposed B-loss	ResNet-50	22.5 K	0.1	-	80.66/-

the 80<sup>th</sup> epoch); image samples were transformed into tensors and normalized with means of [0.491, 0.482, 0.447] and standard deviations of [0.247, 0.243, 0.261].

Some of the experimental settings might differ from those of Xia et al. [25]: the model ensembling technique was applied; a random resized crop with a scale range of [0.8, 0.1] and an aspect ratio range of [0.9, 1.1] was applied to all samples in all sets as a transformation, so test set sampling was implemented using test-time augmentation with a random resized crop; models with the lowest validation loss were used for inference.

All the experiments were performed seven times with random seeds of [42, 0, 17, 9, 3, 16, 2]. The mean and standard deviation of experimental results were then reported. The multiple predictions obtained through model ensembling allowed for the calculation of final predictions using majority voting.

Accuracy was used [12] as metric. The obtained results were not compared with the state-of-the-art results. The latter aggregate multiple techniques and complex network architectures. So, the comparison would be unfair.

Additionally, we conducted an experiment using the ResNet-50 architecture, training only the output layer to reduce computational complexity and focus on the final classification stage. The experiment was performed on noisy data, as this scenario presents a more challenging task for models and allows us to evaluate the robustness of the architecture. To enhance model performance, we applied label smoothing to prevent overfitting and used the B-loss function, which is known for its robustness to noisy labels.

Our experimental results show that all models, except for the ResNet-50 architecture, achieved convergence on the validation set. The highest accuracy was achieved when training the CNN architecture. The best results on clean data were obtained using an ensemble of models trained with the Cross-Entropy (CE) loss function, while on noisy data, the ensemble of models trained with the B-loss function performed the best. We observed overfitting in all experiments using the N-loss function, as well as in the experiment with the CE-loss function on noisy data, evidenced by a significant gap between training and validation loss. In an additional experiment with the ResNet-50 architecture (using the B-loss function), training only the output layer on noisy data yielded results significantly inferior to the CNN architecture. Moreover, the loss function did not converge on the validation set, likely due to the limited training of only the output layer.

## 6 Conclusion

In this work, we investigated the impact of different loss functions on model performance under both clean and noisy data conditions. Our experiments revealed that models trained with the Cross-Entropy (CE) loss function achieved the highest accuracy on clean data, demonstrating its effectiveness in scenarios with reliable annotations. However, when exposed to noisy data, the Brier (B) loss function outperformed other approaches, highlighting its robustness to label noise. In contrast, models trained with the N-loss function, as well as the CE-loss function on noisy data, exhibited overfitting.

The results underscore the importance of selecting appropriate loss functions based on the quality of the data. While CE-loss remains a strong choice for clean datasets, B-loss emerges as a reliable alternative for noisy settings, mitigating the risk of overfitting. These findings provide valuable insights for practitioners working with imperfect datasets, even though our study was conducted in an academic context.

A notable limitation of this work is the computational constraints, which prevented us from reproducing the current state-of-the-art methods for this task. Nevertheless, our results contribute to a clearer understanding of how different loss functions behave under varying data conditions, offering a foundation for future exploration in this area.
